Centrality and Transverse Momentum Dependence of Elliptic Flow of Multistrange Hadrons and $\phi$ Meson in Au + Au Collisions at $\sqrt{s_{NN}} = 200 \text{ GeV}$

We present high precision measurements of elliptic flow near midrapidity ($|y| < 1.0$) for multistrange hadrons and $\phi$ meson as a function of centrality and transverse momentum in Au + Au collisions at center of mass energy $\sqrt{s_{NN}} = 200$ GeV. We observe that the transverse momentum dependence of $\phi$ and $\Omega v_2$ is similar to that of $\pi$ and $p$, respectively, which may indicate that the heavier strange quark flows as strongly as the lighter up and down quarks. This observation constitutes a clear piece of evidence for the development of partonic collectivity in heavy-ion collisions at the top RHIC energy. Number of constituent quark scaling is found to hold within statistical uncertainty for both 0%–30% and 30%–80% collision centrality. There is an indication of the breakdown of previously observed mass ordering between $\phi$ and proton $v_2$ at low transverse momentum in the 0%–30% centrality range, possibly indicating late hadronic interactions affecting the proton $v_2$.

DOI: 10.1103/PhysRevLett.116.062301
At sufficiently high temperature and/or high density, quantum chromodynamics (QCD) predicts a transition from hadronic matter to deconfined partonic matter [1]. The main goal of the STAR (Solenoid Tracker at RHIC) experiment at the Relativistic Heavy Ion Collider (RHIC) is to study the properties of QCD matter at extremely high energy and parton densities, created in the heavy-ion collision. In high energy heavy-ion collisions, particles are produced with an azimuthally anisotropic momentum distribution, which is a result of hydrodynamical flow of the quark-gluon plasma (in the soft regime). One way to examine this anisotropy is to measure elliptic flow $v_2$, which plays a crucial role in the study of the QCD matter formed during the collision. The elliptic flow, defined as $v_2 = \langle \cos 2(\phi - \Psi) \rangle$, is the second Fourier coefficient of the azimuthal distribution of the emitted particle with respect to the reaction plane (defined by the beam axis and a vector between the centers of the colliding ions). Here, $\phi$ is the azimuthal angle of the emitted particle and $\Psi$ is the azimuthal angle of the reaction plane. Over the past decade, experimental measurements have shown elliptic flow to be especially sensitive to the initial phase and equation of state of the system formed in heavy-ion collisions [2–6]. However, information about the early dynamics of the system may be modified by hadronic rescattering in the later stage of the collision [7,8]. The hadronic interaction cross sections of $\phi$, $\Xi$, and $\Omega$ are expected to be small [9] and their freeze-out temperatures are close to the quark-hadron transition temperature predicted by lattice QCD [10,11]. Hence, these hadrons are expected to be small and their freeze-out temperatures are calculated as a function of invariant mass for each $p_T$ and centrality bin in order to take into account the invariant mass dependence of the signal to background ratio. Details of this method can be found in Ref. [24]. The observed $v_2$ values are corrected for finite event plane resolution, which is determined by comparing the two $\eta$-subevent plane angles. A resolution correction is done by dividing the term $\cos 2(\phi - \Psi)$ by the event plane resolution for the corresponding centrality for each event following the method described in Refs. [25,26]. The change in $v_2$ between the present method of resolution correction and the previous method used in earlier STAR publications [4–6] is $\leq 5\%$ at $\sqrt{s_{NN}} = 200$ GeV. Here, $\Psi$ is the second order event plane which is used for $v_2$ measurements.

For all particle species, the cuts used for particle identification (PID) and background subtraction are varied to estimate the systematic errors. Furthermore, different techniques (e.g., by counting entries in each bin of the invariant mass histogram or by fitting the shape of the invariant mass distribution using a function) for yield extraction are used. For $\pi^\pm$, $K^\pm$, and $p(\bar{p})$, six different combinations of track cuts and three different sets of PID cuts which finally yield 18 combinations have been used. For other strange hadrons ($K_S^0$, $\phi$, $\Lambda$, $\Xi$, and $\Omega$) 20 different cut combination are used. The root-mean-square value of point-by-point difference from the default value ($v_2$ from the default set of cuts) is used as the systematic error on each data point. The total systematic error depends on $p_T$, centrality, and particle species. We observed 3–5% systematic error for $p_T < 1.5$ GeV/c and 0–30% centrality for $\phi$, $K_S^0$, $\Lambda$, whereas for $\Xi$ and $\Omega$ the systematic error varies from 8% to 14%. Total systematic errors are less than 1% for $\pi^\pm$, $K^\pm$, and $p(\bar{p})$ for all $p_T$'s and centralities.

We investigated the effect of track reconstruction efficiency on the measured $v_2$ of identified hadrons for wide centrality bins, such as 0–80% centrality bin. The centrality dependence of track reconstruction efficiency varies the measured $v_2$ toward events with higher reconstruction efficiency, an effect we will refer to as an “efficiency bias.” Because of the efficiency bias, the $v_2$ of $\Xi$ and $\Omega$, each having three daughters, changes by no more than 5% in 0–80% centrality. For the other measured particles, the effect is less than 3% for 0–80% centrality.
The $v_2(p_T)$'s of all particles presented here have been corrected for the efficiency bias by using the inverse of efficiency as a weight for the $v_2$ as a function of $p_T$ and centrality.

An additional correction is needed for $\phi, \Xi, \text{and } \Omega v_2$. An event bias is naturally introduced when one measures $v_2$'s in wide centrality bins, especially for the rare particles. As the measured $v_2$ is an average over all events weighted by the particle yield, the average event shape depends on the particle type. A Glauber model [19] study of the average initial participant eccentricity indicates that the multi-strange hadron $v_2$ is more biased toward central events than that of the light and strange hadrons. Specifically, the average eccentricity for multistrange hadrons in wide centrality bins is smaller than the eccentricity determined by the particle yield of all charged hadrons. One should take this effect into consideration if any conclusion on number of constituent quark scaling is drawn. This bias can be corrected by normalizing the measured $v_2$ by the ratio of eccentricity to that weighted by the yield of the particle of interest. We find the event bias correction factors for the 0%–30%, 30%–80%, and 0%–80% centralities are 1.002, 1.053, and 1.028 for $\phi$, 1.019, 1.054, and 1.091 for $\Xi$, and 1.068, 1.067, and 1.177 for $\Omega$. The event bias correction for light and strange hadrons is small (< 0.03), perhaps due to their copious production. Therefore, in the later discussion of number of constituent quark (NCQ) scaling, the event bias correction is applied only to the $v_2$'s of multistrange hadrons and $\phi$ meson. The above correction factors remain almost unchanged if we use a color-glass condensate [27] based model to calculate eccentricity.

In Fig. 1 we present the elliptic flow parameter $v_2(p_T)$ at midrapidity ($|y| < 1.0$) for (a) $\Xi^- + \Xi^+$, (b) $\Omega^- + \Omega^+$, and (c) $\phi$ in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV for 0%–30% and 30%–80% centrality. Event bias correction factors have been applied to the results shown in Fig. 1. A clear centrality dependence of $v_2(p_T)$ is observed for $\phi, \Xi,$ and $\Omega$, similar to that of identified light and strange hadrons previously measured by the STAR experiment [28]. The values of $v_2$ are found to be larger in peripheral collisions (30%–80% centrality) compared to those in central collisions (0%–30% centrality). This observation is consistent with an interpretation in which the final momentum anisotropy is driven by the initial spatial anisotropy.

The NCQ scaling in $v_2$ for different identified hadrons is considered to be a good probe for studying the strongly interacting partonic matter. The observed NCQ scaling of identified hadrons in experimental data [29] indicates the importance of parton recombination in forming hadrons in the intermediate $p_T$ range (2.0 GeV/c < $p_T$ < 4.0 GeV/c) [30–33]. Such scaling may indicate that collective elliptic flow develops during the partonic phase. Previous measurements have found that $v_2$'s of $\pi, K, p, K^0_S, \Lambda, \Xi,$ and $\phi$ follow NCQ scaling well at the top of the RHIC energy ($\sqrt{s_{NN}} = 200$ GeV) [29]. The large statistics data sets collected by STAR detectors allow us to measure elliptic flow of multistrange hadrons, specifically that of the $\Omega$ baryon which is made of pure strange (s) or antistrange ($\bar{s}$) constituent quarks and of the $\phi$ meson, consisting of one s and one $\bar{s}$ constituent quark.

Figure 2 shows the $v_2$ as a function of $p_T$ for $\pi, p, \phi,$ and $\Omega$ for 0%–80% centrality in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV. Here, $\phi$ and $\Omega$ $v_2$ are corrected for the event bias mentioned earlier. Figure 2(a) shows a comparison between the $v_2$'s of $\pi$ and $p$ consisting of up ($u$) and down ($d$) light quarks, and Fig. 2(b) shows a comparison of the $v_2$'s of $\phi$ and $\Omega$ containing heavier s quarks. The $v_2$'s of $\phi$ and $\Omega$ are mass ordered at low $p_T$ and a baryon-meson separation is observed at intermediate $p_T$. It is clear from Fig. 2 that the $v_2(p_T)$ of hadrons consisting only of strange quarks ($\phi$ and $\Omega$) is similar to that of $\pi$ and $p$. However, unlike $\pi$ and $p$, the $\phi$ and $\Omega$ do not participate strongly in the hadronic interactions, which suggests that the major part of collectivity is developed during the partonic phase in Au + Au collisions at $\sqrt{s_{NN}} = 200$ GeV.

We now compare our results for NCQ scaling for different collision centrality classes to see how the partonic collectivity changes with system size. Figure 3 shows the
FIG. 3. Panel (a) and (b) show $v_2$ scaled by number of constituent quarks ($n_q$) as a function of $p_T/n_q$ for 0–30% and 30–80% collision centrality, respectively. Panel (c) and (d) show $v_2$ scaled by number of constituent quarks ($n_q$) as a function of $(m_T - m_0)/n_q$ for 0–30% and 30–80% collision centrality, respectively. Ratios with respect to a polynomial fit to the $K_S^0$ $v_2$ are shown in the corresponding lower panels. Vertical lines are statistical uncertainties and shaded boxes are systematic uncertainties.

$v_2$ scaled by number of constituent quarks ($n_q$) as a function of $p_T/n_q$ and $(m_T - m_0)/n_q$ for identified hadrons from Au+Au collisions at $\sqrt{s_{NN}} = 200$ GeV for 0%–30% and 30%–80% centrality, where $m_T$ and $m_0$ are the transverse mass and the rest mass of the hadron, respectively. Here, $\phi$, $\Xi$, and $\Omega$ $v_2$ are corrected for the event bias mentioned above. To quantify the deviation from NCQ scaling, we fit the $K_S^0$ $v_2$ with a third-order polynomial function. We then take the ratio of $v_2$ for the other measured hadrons to the $K_S^0$ fit. The ratios are shown in the lower panels of Fig. 3. Table I shows the deviations of the $\phi$, $\Lambda$, $\Xi$, and $\Omega$ $v_2$'s from the $K_S^0$ fit line in the range $(m_T - m_0)/n_q > 0.8$ GeV/$c^2$.

For both the 0%–30% and 30%–80% centralities, the scaling holds within approximately 10%, excluding the pions. The deviation of the pions could be due to the effect of resonance decay and nonflow correlations [34]. We have seen a similar order (~10%) of deviation when using $p_T/n_q$ scaling as a reference. The maximum deviation from NCQ scaling is ~20% at $\sqrt{s_{NN}} = 2.76$ TeV, as observed by the ALICE experiment [35]. Therefore, at top RHIC energy, NCQ scaling holds better than LHC energy. The observed difference between the charged kaon and $K_S^0$ $v_2$ at low $p_T$ is due to differences in the pileup protection conditions used in collecting the different data sets. The difference is taken to be an additional contribution to the systematic error on $K_S^0$ $v_2$.

Hydrodynamical model calculations predict that $v_2$ as a function of $p_T$ follows mass ordering, where the $v_2$ of heavier hadrons is lower than that of lighter hadrons and vice versa [36,37]. Mass ordering is indeed observed in the identified hadron $v_2$ measured in the low $p_T$ region ($p_T \leq 1.5$ GeV/$c$) [28]. Recent phenomenological calculations, based on ideal hydrodynamics together with a hadron cascade (JAM), show that the mass ordering of $v_2$ could be broken between $\phi$ mesons and protons at low $p_T$ ($p_T < 1.5$ GeV/$c$) [7,8]. The broken mass ordering is thought to be due to late-stage hadronic rescattering effects on the proton $v_2$ since the model calculations assume a low hadronic cross section for the $\phi$ but a large hadronic cross section for the proton.

The ratios of $\phi$ $v_2$ and proton $v_2$ are shown in Fig. 4. The ratios are larger than unity at $p_T \sim 0.5$ GeV/$c$ for 0%–30% centrality showing an indication of breakdown of the expected mass ordering in that momentum range. This could be due to a large effect of hadronic rescattering on the proton $v_2$, indicated by the shaded red band in Fig. 4(a). We have also considered the effect of the momentum resolution and energy loss of the TPC as well as the decay (feed-down) effects on the proton $v_2$. Our study, based on the UrQMD framework, indicates that the momentum resolution and decay effects on the ratio of $v_2(\phi)$ to $v_2(p)$ in the measured momentum region are negligible. The breakdown of mass ordering of $v_2$ is more pronounced in the 0%–30% than the 30%–80% centrality. For example, the ratio $v_2(\phi)/v_2(p)$ is $4.35 \pm 0.98^{+0.66}_{-0.45}$ at $p_T = 0.52$ GeV/$c$ in 0%–30%, while it is $1.12 \pm 0.10^{+0.047}_{-0.053}$ in 30%–80%. In the

central events, both hadronic and partonic interactions are larger than in peripheral events. Therefore, the combined effects of large partonic collectivity on the $v_2$ and significant late-stage hadronic interactions on the proton $v_2$ produce a greater breakdown of mass ordering in the 0%-30% centrality data than in the 30%-80% [15]. This observation indirectly supports the idea of a small hadronic interaction cross section for the $φ$ meson. We have also studied the ratio of $φ$ $v_2$ to proton $v_2$ using the transport models AMPT [38] and UrQMD [39]. The $v_2(φ)/v_2(p)$ ratios for 0%-30% centrality from the AMPT and UrQMD models are shown in Fig. 4(b). The black shaded band is from AMPT with a hadronic cascade time of 0.6 fm/c, while the yellow band is for a hadronic cascade time of 30 fm/c. It is clear from Fig. 4(b) that with increasing hadronic cascade time (and therefore more hadronic rescattering), the $v_2(φ)/v_2(p)$ ratio increases. This is attributed to a decrease in the proton $v_2$ due to an increase in hadronic rescattering, while the $φ$-meson $v_2$ remains unaffected [15]. The ratios from UrQMD are shown as a red shaded band which is much smaller than unity. The UrQMD model lacks partonic collectivity and therefore does not fully develop the $φ$-meson $v_2$.

In summary, we have reported high-statistics elliptic flow measurements for multistrange hadrons ($Ω$ and $Ω'$) and $φ$ meson with other light and strange hadrons ($π$, $K$, $K^0$, $p$, and $Λ$) in $Au + Au$ collisions at $\sqrt{s_{NN}} = 200$ GeV for different centralities. The $p_T$ dependence of $φ$ and $Ω$ $v_2$ is observed to be similar to that of $π$ and $p$, indicating that a large amount of collectivity is developed in the initial partonic phase for light and strange hadrons. NCQ scaling holds within the statistical uncertainty for both 0%-30% and 30%-80% centralities, suggesting collective motion of quarks prior to hadronization. The comparison between the $φ$ and $p$ $v_2$ shows that, at low $p_T$, there is a possible violation of hydrodynamics-inspired mass ordering between $φ$ and $p$. Model calculations suggest that the $p_T$ dependence of $v_2(φ)/v_2(p)$ can be qualitatively explained by the effect of late-stage hadronic rescattering on the proton $v_2$ [7,8].
