Abstract

Xanthogranulomatous pyelonephritis (XGP) is characterized by the presence of lipid-laden foam cells with both acute and chronic inflammatory cells. The aim of the study is to present our experience about patients with Xanthogranulomatous pyelonephritis. 29 patients were evaluated through a complete anamnesis and the preoperative management included routine blood and biochemical tests, urine culture, and renal ultrasound, intravenous urography, and computed tomography (CT). All patients underwent open nephrectomy followed by the pathological exam. The main symptoms of these patients were fever and flank pain. Preoperative laboratory tests revealed anemia, leukocytosis, and increasing levels of blood urea nitrogen (BUN) and creatinine. Kidney failure was noticed in almost half of the cases. This study succeeded to evaluate the demographic, clinical, biological, surgical, and histological characteristics. A pathological diagnosis is mandatory mainly for the evaluation of its coexistence with renal carcinoma.

Keywords:
- Xanthogranulomatous pyelonephritis
- urinary tract infection
- E. Coli
- anemia
- leukocytosis
- nephrectomy

Highlights

- Xanthogranulomatous pyelonephritis (XGP) occurs due to recurrent chronic infection secondary to renal lithiasis and it is frequently underdiagnosed due to its unspecific symptoms which mimic other conditions.
- CT is considered the imaging technique of choice in the diagnosis of the disease preoperatively and a plethora of CT characteristics have been described so far.
- A diagnosis of certainty is mandatory to be pathological, which is useful not only in the confirmation of the disease, but also in the evaluation of its coexistence with renal carcinoma.

Introduction

Xanthogranulomatous pyelonephritis (XGP) is a chronic inflammation of the renal parenchyma, which was first described in 1916 by Schlagenhaufer and it occurs in approximately 1% of all renal infections. Two major forms can be recognized: diffuse and focal (1). Some authors also describe the segmental xanthogranulomatous pyelonephritis which involves only a segment of the kidney. The diffuse form can be easily confused with a severe abscess or pyonephrosis, while the focal form is called pseudotumoral because it is usually confused with a renal tumor.

It generally occurs due to recurrent chronic infection secondary to renal lithiasis which usually leads to obstruction. The infection is usually associated with Proteus or E. Coli, but Pseudomonas is also frequently involved (2). Other agents identified are Staphylococcus aureus, Candida, Bacteroides, group B Streptococcus or Klebsiella. Although nephrolithiasis is usually present, it is not mandatory for diagnosis. The xanthogranulomatous pyelonephritis behaves like a pseudo tumor capable of local invasion and destruction, starting with the kidney, continuing with perinephric fat and, if left untreated, involving the adjacent retroperitoneal structures (3, 4).

Histologically, the condition is characterized by the presence of lipid-laden foamy macrophages with both acute and chronic phase inflammatory cells. Focal abscesses may be present.

In most cases, men are affected less than women, with a female to men ratio of 5:1 (5). Regarding the preoperative diagnosis, XGP is frequently underdiagnosed due to its unspecific symptoms which mimic other conditions such as perinephric abscess, pyelonephritis or renal tuberculosis. There is no single clinical or radiologic element of diagnosis specific to xanthogranulomatous pyelonephritis (6). Symptoms include fever, flank pain, lower urinary tract symptoms, hematuria or weight loss. 30% of patients presented complications such as paranephric abscess, nephrocolonic or nephrocutaneous fistula (7).

Usually, the transabdominal ultrasound evaluation is used to assess the disease. Signs such as hydronephrosis, less parenchymal tissue, staghorn calculus, often indicate a diffuse form, while there are no specific lesions for a focal form. CT findings are strong indicators that reveal helpful information about local and regional involvement. Nowadays, CT is considered the chosen imaging procedure for the preoperative diagnosis of the disease, numerous CT characteristics having been described so far. The most typical CT features of XGP should be considered: low-density fluid-filled areas within the renal parenchyma and additional elements indicating perinephric extension. Studies describe the MRI evaluation as a sensitive method in identifying lipid-laden foamy macrophages (6).

The treatment for the diffuse form of the disease is usually nephrectomy. For the focal form, patients who have contraindications for surgery or bilateral form of the disease, antibiotics are the key to the treatment if there is any diagnosis based on biopsy or combined cytological and clinical features (8). The prognosis is considered reasonable after the treatment. Death from Xantogranulomatous pyelonephritis is exceedingly rare, although morbidity is substantial. Transitional cell carcinoma located in the renal pelvis has been associated with the disease.

The goal of the study is to present our experience with patients diagnosed with XGP in our clinic and to evaluate the demographic, clinical, paraclinical, surgical and histological characteristics of this series of patients, for a better understanding and knowledge of the disease.

Materials and Methods

We conducted a retrospective observational study from January 2013 to December 2017 that identified 29 patients diagnosed with XGP histologically confirmed who have been treated in our clinic (9). Moreover, patients with Xanthogranulomatous pyelonephritis associated with renal carcinoma have also been included. All patients were evaluated through a complete anamnestic and a rigorous physical exam. Preoperative management included routine blood tests and biochemical urine tests, summary and urinalysis (10). Also, all patients underwent renal ultrasound, intravenous urography and computerized tomography – Figure 1. Patients with low excretory functions at the intravenous urography underwent renal scintigraphy with Tc99m-DTPA to confirm the non-functioning kidney and to evaluate the function of the other kidney. Any urinary tract infection was treated with antibiotics before the surgical intervention, or depending on the severity of the case, the patients underwent percutaneous nephrostomy or Cook stent (double JJ stent) insertion.

The parameters considered were: age, sex, complete blood tests, urine tests, symptoms at presentation such as fever and pain location, affected sides, surgical method and pathological exam. All collected data were analyzed and interpreted using Microsoft Word 2013 and Microsoft Excel 2013. Simple descriptive statistics were calculated (11-13).
Xanthogranulomatous pyelonephritis

Figure 1. CT pelvic scans in a patient with xanthogranulomatous pyelonephritis highlighting the invasion of the disease.

All patients underwent nephrectomy, followed by the pathological exam in order to confirm the diagnosis. The tissue samples were placed in formaldehyde and then hematoxylin eosin stain was used for microscopical observations. The diagnosis of XGP was made due to the presence of diffuse or focal inflammatory processes with lipid-laden macrophages and chronic granulomatous inflammation – Figure 2. Postoperatively, the lab tests were repeated and the patients were carefully monitored.

Figure 2. The pathological examination of XGP made from inflammatory lymphoplasmocitary infiltrate and abundant xantomate cell, HE stain.

Results and Discussions

The statistical analysis of our database comprising 29 patients treated in our hospital revealed that there were 25 women (86.2%) and only 4 men (13.8%), with a female to male ratio of 6.1:1, with a mean age of 54.93 years – Table 1. More than a half (51.72%) were aged between 40 and 60, over one third (37.93%) between 60 and 80 and only 10.34% were aged under 40, similar results being reported in a study performed in Argentina (14).

As many authors consider, the main symptoms are flank pain and fever. In our study, unilateral flank pain was the main presentation symptom (89.65%) followed by fever (55.17%). In more than a half (51.72%) of the patients, flank pain and fever coexisted at first presentation. Close values are found in related studies (2). The pain of XGP is not colicky in nature; it is usually dull and persistent (15).

In the following chart, we noted that the main symptom for which patients were admitted to our hospital was a combination of fever and flank pain in 15 cases, flank pain in only 11 cases, two of them being asymptomatic and one presenting fever only – Figure 3.

Figure 3. Column chart representing the patients’ symptoms at presentation.
Preoperative lab test revealed anemia in 19 patients, leukocytosis in 15 patients and increasing levels of blood urea nitrogen and creatinine in 13 cases. The mean hemoglobin value before surgery was 11.5 ± 1.9 g/dL, and the mean value of leukocytes was 10.6 ± 3.6 x 10^3/μL. One mechanism of anemia suggested by Goodman and co. (16) would be a defect in the reutilization of iron.

As shown in Table 2, the simultaneous presence of anemia and leukocytosis was noticed in more than one third of the patients, but also a high number of patients did not present anemia nor leukocytosis.

A creatinine increase over 1.0 mg/dL (F) and over 1.2 mg/dL (M) was detected preoperatively in 13 patients (44.82%). The mean level of creatinine was 1.03 ± 0.26 mg/dL, and the mean level of GFR was 63 ± 18 mL/min/1.73 m². Kidney failure was noticed in 13 (44.82%) out of the 29 cases with a GFR < 60 mL/min/1.73 m², but more than half of the patients (55.17%) presented normal kidney function.

The urine culture was positive in 18 patients (62.06%) and negative in over one third of them (37.84%). In 16 out of the 18 cases with positive urine culture, a Gram-negative microorganism from the Enterobacteriaceae family was detected, while Gram-positive microorganisms were detected in only two cases (6.89%). Our findings are consistent with those reported by a study conducted in Greece (17), in terms of the urine culture results.

As shown in the following column chart – Figure 4, the most frequent microorganism identified was E. Coli, followed by Proteus, Klebsiella, Enterococcus and Staphylococcus, while a significant number of patients had sterile urine.

Figure 4. The distributions of the uropathogens identified in urine cultures

In the following column chart – Figure 5, the strong relationship between renal lithiasis and/or urinary tract infections with Xanthogranulomatous pyelonephritis is represented.

Figure 5. The association of urinary tract infections (UTI) and renal lithiasis in the study group

Our study limitations reside in the retrospective observational nature, the lack of standardized protocol, the progression of the chronic renal disease after the surgical treatment that could not been demonstrated and the low number of cases presented in the study in accordance with the disease prevalence.

It is generally accepted that XGP is caused by a combination of diseases which includes obstructive lithiasis and chronical infections (5). Persistent stasis yields recurrent infections with subsequent coagulative necrosis and destruction of the renal parenchyma. In our study, renal lithiasis was found in 21 cases (72.41%), which is a strong argument to support the etiopathogenic theory, but we also enrolled 2 patients in which no urinary tract infection or renal calculi were found.

The inflammatory process affects the whole kidney, the focal forms being extremely seldom discovered (18-20). Owing to its heterogeneous appearance, XGP can easily be confused with renal cell carcinoma and/or infiltrating urothelial carcinoma of the renal pelvis. There are no findings to support the idea of a bilateral disease, and no predilection for one side only, the percentages
being almost equal for both left or right sides (7). In this study, we had 16 cases of xanthogranulomatous pyelonephritis located on the right side (55.17%), but the number of cases and the low percentage cannot support the predominance of this side.

The treatment for XGP is surgical, including open or laparoscopic nephrectomy. Because of the clinical and paraclinical exam, preoperative care should be considered, and it often includes antibiotics and renal drainage (by means of nephrostomy or JJ stent), in combination or separately (21). The authors of a study describe renal drainage using nephrostomy in 77.8% of the overall 30 cases (2).

The preoperative treatment consisted only in antibiotics in 13 cases (44.82%), while in more than a half of the cases (55.17%) it was followed by drainage: 13 patients (44.82%) with percutaneous nephrostomy and 3 patients (10.34%) with JJ stent.

Regarding the surgical approach, open nephrectomy was performed in 21 cases (72.41%), similar to the report of a study which analyzed nephrectomy in inflammatory renal disease in Brazil (22). Laparoscopic nephrectomy was performed in 7 cases (24.13%) and partial nephrectomy was the treatment of choice in only one case (3.44%).

The laparoscopic treatment was frequently disputed, but some studies describe that a good experience in laparoscopy can make this kind of intervention possible also in xanthogranulomatous pyelonephritis (23). Laparoscopic nephrectomy for XGP is complicated and more technically demanding than the laparoscopic nephrectomy for noninfectious etiologies (24). For the novice laparoscopist, however, the open approach should remain the approach of choice.

Postoperative blood tests revealed anemia in 25 cases (86.2%), leukocytosis in 12 cases (41.37 %) and the presence of kidney failure (eGFR <60 mL/min/1.73 m²) in 13 patients (44.82%).

The examination of the excisional specimen (post-nephrectomy) revealed the presence of Xanthogranulomatous pyelonephritis, with characteristic chronic inflammatory infiltration and lipid-laden macrophages in all 29 cases – Figure 6. This is in conformity with the results of the research conducted by Arvind and co. (25, 26). The pathological examination revealed the presence of XGP in only 23 cases (79.31%), but it revealed the presence of the XGP simultaneous with renal carcinoma in six cases (20.68%).

Figure 6. The macroscopic evaluation of the post-nephrectomy specimen

Conclusions

Our study succeeded in evaluating the demographic, clinical, paraclinical, surgical and histological characteristics of this series of patients. Moreover, the results of the study were compared with the data from other studies. Xanthogranulomatous pyelonephritis affects mostly women (a W:M ratio up to 6:1) aged between 40 and 70 years.

The main symptoms are flank pain and fever, occasionally patients can be asymptomatic. Blood laboratory tests reveal mainly anemia, leukocytosis and kidney failure. The most frequent microorganism found in urine was E. Coli. The treatment was surgical (nephrectomy) in most cases, associated with antibiotic therapy. Antibiotics alone cannot control the disease, but associated with surgical therapy, they can prevent pre- and postoperative complications.

The diagnosis of certainty is mandatory to be pathological, which is useful not only in the confirmation of the disease, but also in the evaluation of its coexistence with renal carcinoma.
